We investigate the dynamics of nuclear fission, assuming purely diffusive motion up to the saddle point. The resulting Smoluchowski equation is solved for conditions appropriate to the $^{16}$O+$^{140}$Nd$\rightarrow$$^{156}$Er reaction at 207 MeV. The solution is characterized by an equilibration time $\tau_0$ for the system to reach steady state, and the fission decay rate in steady state, $\Lambda$. We find that the equilibration time $\tau_0$ plays a very small role in determining the number of prescission neutrons. The diffusion coefficient extracted from the experimental data is larger than the theoretical in the work of Bush, Bertsch, and Brown by a factor of 5–11.

PACS number(s): 24.75.+i, 24.60.Ky

It is necessary to understand the dynamics of large amplitude shape change in order to describe a number of processes for which the statistical model fails. This includes several effects associated with fission, including the emission of prescission neutrons [1–3] and the emission of giant dipole photons [4]. On the theoretical side, large amplitude shape dynamics is most commonly treated assuming the average motion can be described by Newtonian mechanics with inertial and linear friction parameters [5]. Recently, Bush, Bertsch, and Brown proposed a model of the shape dynamics of highly excited nuclei from quite a different point of view [6]. They start with the basic assumption that the highly excited nucleus can be described as an incoherent mixture of Hartree-Fock configurations at a given energy. They concentrate exclusively on the diffusion in the nuclear shape degrees of freedom avoiding a discussion of inertia, friction, or indeed any collectivity in the motion. Based on this picture, they have calculated the diffusion coefficient for quadrupolar shape fluctuations using the residual interaction to mix Hartree-Fock configurations.

In frictional dynamics, the Kramers' theory [7] may be used to find the fission decay rates. A corresponding theory can be derived from the diffusive dynamics using the Smoluchowski equation. We show how this is done below. The end result is equivalent to the Kramers' theory, in the strongly overdamped limit of that theory. We then discuss the numerical application to prescission neutron multiplicities. In Ref. [6], the theoretical diffusion rate was an order of magnitude slower than found in the analysis of Ref. [2]. Our analysis here of the measurement of Ref. [3] is a factor of 5 different from the theoretical prediction, due mostly to the larger number of prescission neutrons extracted from the later experiment.

We start from a generic rate equation

$$\frac{dP_i}{dt} = - (\Gamma_{i,i-1} + \Gamma_{i,i+1}) P_i + \Gamma_{i-1,i} P_{i-1} + \Gamma_{i+1,i} P_{i+1},$$

where $P_i$ is the probability of finding the system in the state $i$ and $\Gamma_{i,j}$ is the rate at which the system moves from one state to its immediate neighbor. This is a generalization of the treatment of Ref. [6], which assumed all $\Gamma_{i,j}$ equal. To be more realistic, we have to consider the effect of the level density on the rates. Detailed balance requires that $\Gamma_{i,j}$ and $\Gamma_{j,i}$ be in the ratio of the final-state level densities $\rho_j$ and $\rho_i$. In terms of these level densities, the rate equation may be expressed

$$\frac{dP_i}{dt} = - v (\rho_{i-1} P_i + \rho_i P_{i-1} - \rho_i P_i - \rho_{i+1} P_{i+1}),$$

where $v$ is a constant. To reduce the above to the Smoluchowski equation, we assume that the states $i$ are uniformly separated in deformation by an amount $\Delta\beta$ and treat $P$ as a continuous function of $\beta$. The finite differences are expanded $P_{i+1} = P_i + \Delta\beta \partial P / \partial \beta$, etc. The result to order $(\Delta\beta)^2$ is the Smoluchowski equation,

$$\frac{dP}{dt} = - \frac{\partial}{\partial \beta} \Big{\frac{\partial V}{\partial \beta} \Big{\frac{1}{T} \frac{\delta \langle P \rangle}{\delta \beta} \Big{}} + D_\beta \frac{\delta^2 P}{\delta \beta^2},$$

where the diffusion coefficient $D_\beta$ may be expressed in terms of microscopic quantities (such as the residual interaction $V_{ij}$) as [6]

$$D_\beta = \frac{2\pi}{\hbar} \sum_j (\beta_i - \beta_j)^2 |V_{ij}|^2 \delta(E_j - E).$$

In deriving Eq. (1), we have also defined the temperature as the inverse logarithmic derivative of the level density and used the chain rule, $\partial \rho / \partial \beta = (\partial \rho / \partial E^*) (\partial E^* / \partial \beta)$. Several authors have applied the Smoluchowski equation to nuclear fission processes with the fission variable as the generalized coordinate [8,9]. It is interesting to note that the fluctuation-dissipation theorem, relating the coefficient of the drift term to that of the fluctuation term, follows directly from the above derivation.

A convenient feature of Eq. (1) is that the diffusion coefficient can be scaled out of the equation by defining a
new time variable $\tau = D\beta t$. Thus we need only solve the equation with $D\beta = 1$ and all solutions corresponding to different $D\beta$'s can be obtained simply by rescaling the time. This scaling property is well known in previous studies using the Smoluchowski equation [8,9]. We will calculate the decay rate by considering the probability current $I(\beta, t)$ which crosses $\beta$ at time $t$. This may be expressed as

$$I(\beta, t) = D\beta \left[ \frac{1}{T} \left( \frac{\partial V}{\partial \beta} \right) P + \frac{\partial P}{\partial \beta} \right].$$

(2)

The decay rate $\lambda$ is defined

$$\lambda(\beta, t) = \frac{I(\beta, t)}{\int_{-\infty}^{\beta} d\beta' P(\beta')}.$$  

It is seen to obey the same scaling, $\lambda(D\beta) = \Lambda D\beta$, where $\Lambda$ is the decay rate for $D\beta = 1$.

The stationary decay rate for Eq. (1) for a particle trapped inside a parabolic barrier has been derived by Chandrasekhar [10]. Assume the potential $V(\beta)$ has a parabolic shape, upward-curving near the equilibrium deformation $\beta_1$ and downward-curving near the barrier top at $\beta_2$.

$$V(\beta) = \begin{cases} \frac{1}{2}k_1(\beta - \beta_1)^2 & \text{when } \beta \leq a, \\ U_B - \frac{1}{2}k_2(\beta - \beta_2)^2 & \text{when } \beta > a. \end{cases}$$

(3)

Here $U_B$ is the barrier height, and the parameter $a$ is determined to make the parabolas join smoothly. Then the stationary value $\Lambda_0$ of the decay rate is simply given in terms of the oscillator parameters and the barrier height by [10]

$$\Lambda_0 = \frac{\sqrt{k_1k_2}}{2\pi T} \exp \left[ -\frac{U_B}{T} \right].$$

(4)

This result can be compared with Kramers' stationary decay rate [7,11]

$$\lambda_k = \frac{\omega_1}{2\pi} \left[ 1 + \frac{\gamma}{2\omega_2} \right]^{1/2} \exp \left[ -\frac{U_B}{T} \right],$$

where $\gamma$ is the reduced friction coefficient. To connect this with Eq. (4), we explicitly introduce the inertial parameter $M$ in the Kramers' formula. The oscillator frequencies $\omega$ are expressed as $\omega_i = \sqrt{k_i/M}$. The reduced friction coefficient $\gamma$ is related to the diffusion coefficient by the Einstein relation [12], $\gamma M = T/D\beta$. Then in the limit of large $\gamma$ the Kramers' formula reduces to

$$\lambda_k \approx \frac{\omega_1\omega_2}{2\pi\gamma} \exp \left[ -\frac{U_B}{T} \right] = \frac{\sqrt{k_1k_2}}{2\pi\gamma M} \exp \left[ -\frac{U_B}{T} \right] = \frac{\sqrt{k_1k_2}}{2\pi T} D\beta \exp \left[ -\frac{U_B}{T} \right]$$

identical to Eq. (4).

We now display some of the characteristics of the solution of the Smoluchowski equation. We choose parameters corresponding to the nucleus $^{158}\text{Er}$ following Ref. [13]. The decay rate is most sensitive to the height of the fission barrier $U_B$ and the difference $\beta = \beta_2 - \beta_1$ between the yrast state and the saddle-point deformations. The fission barrier height is quoted in Ref. [13] for a range of angular momenta and we use those, interpolating or extrapolating to angular momenta not included in their table. The deformation at the saddle point is determined using their Fig. 2, which shows the barrier as a function of the separation of the two mass centers. To convert to an equivalent deformation $\beta$, we demand that quadrupole moments be the same as for a spheroid with the deformation $\beta_2$. This procedure is rough, but high accuracy is not possible without a more detailed consideration of the fission path when calculating the diffusion coefficient. The saddle-point deformation does not depend strongly on angular momentum; we take a fixed value $\beta_2 = 1.20$. The yrast deformation $\beta_1$ is determined from the rotating liquid drop model. This also does not depend strongly on angular momentum for the range considered; our value here is $\beta_1 = 0.42$. The potential-energy function is shown in Fig. 1 and the values of the parameters are given in Table I.

We now describe the results of numerical solution of the Smoluchowski equation. We assume an initial probability density

$$P(\beta, 0) \propto \exp \left[ -\frac{V(\beta)}{T_0} \right]$$

with $T_0 = 0.3$ MeV as suggested in Ref. [14]. In Fig. 2,
we plot time evolution of $P(\beta, \tau)$ for $^{158}\text{Er}$ at $J = 65\hbar$ and $T = 2.5$ MeV as a function of $\tau$ in two cases, (a) with and (b) without the fission barrier. The point of this comparison is to show that the system reaches a stationary decaying state in one case but not in the other. The location of the saddle point is indicated by an arrow in the figures. The two cases (a) and (b) are clearly distinguished in Fig. 2 where the role of the fission barrier becomes especially transparent.

We mention briefly the sensitivity of the decay rate to the parametrization of Eq. (3). According to Eq. (4), the stationary value $\Lambda_0$ of the decay rate depends on the barrier height $U_B$ and the nuclear temperature as well as the oscillator parameters $k_i$. In our calculations, we have used two parabolas with the same oscillator parameters $k_1 = k_2$. Once $U_B$ and $\beta$, are fixed, there is not much room left to vary the oscillator parameters. Moreover, $\sqrt{k_1 k_2}$ and hence $\Lambda_0$ is not affected by more than just a few percent even though we change the ratio $k_1 / k_2$ as much as possible. We therefore judged it sufficient to take the parabolas with the same oscillator parameter in our main calculations.

In Fig. 3, we show the calculated $\Lambda(\tau)$ across the saddle point as a function of $\tau$ for two cases, $J = 65\hbar$ and $72\hbar$ of $^{158}\text{Er}$. In this figure, we can clearly see the transient behavior and the saturation of decay rate which occur under the influence of fission barrier. On the other hand, the decay rate calculated from the pure diffusion equation

\begin{table}
\centering

\end{tabular}
\caption{Values of temperature ($T$), oscillator parameter ($k$), and barrier height ($U_B$) adopted for the potential-energy function plotted in Fig. 1 and used in calculations of the stationary value of decay rate ($\Lambda_0$) for various spins and nuclei. The decay rate ($\Lambda_0^{bc}$) in the sixth column is evaluated by Eq. (4) and the decay rate ($\Lambda_0^{num}$) in the last column is from the solution of the Smoluchowski equation.}
\end{table}
without any fission barrier does not show any evidence for saturation, as can be seen from the dashed line in Fig. 3. But note the over-shooting of the decay rate at higher partial waves, which has been also discussed by Lu et al. [15]. In the last two columns of Table I, we list the stationary values of decay rate \( \lambda^0_0 \) which is evaluated using Eq. (4) and \( \lambda^{\text{stat}}_0 \) which is obtained from our numerical calculations. The stationary value \( \lambda_0 \) of the fission decay rate shows a strong dependence on \( \Lambda \) for fixed \( J \) and also a strong dependence on \( J \) for fixed \( \Lambda \). However, the origin for such dependence in two cases is quite different. In Table I, we also list the nuclear temperature \( T \) together with the potential parameters. When \( J \) is fixed, the main reason \( \lambda_0 \) decreases as \( A \) becomes smaller is the decrease in \( T \) due to the cooling by neutron evaporation. Here the shape of the potential barrier remains more or less the same for all the nuclei participating in the chain. On the contrary, when \( A \) is fixed, the temperature does not depend on \( J \) very much, but the barrier height changes with \( J \), giving a larger rate \( \lambda_0 \) for larger \( J \).

The equilibration time \( \tau_0 \) may be defined by the time interval until \( \Lambda \) reaches its stationary value. The \( \tau_0 \) is found to exist more or less the same value \( \tau_0 = 0.068 \) for all \( J \)'s and for all \( A \)'s. This also corresponds to an extremum point in the dashed line (without the fission barrier) of Fig. 3 where \( \tau_0 \) is indicated by an arrow. Our result suggests that \( \tau_0 \) does not depend on \( T \) nor the shape of the potential. The equilibration time \( \tau_0 \) which corresponds to a specific \( D_B \) can be found from the scaling \( t_0 = \tau_0 / D_B \). Therefore, \( t_0 \) is inversely proportional to \( D_B \) and hence proportional to the reduced friction coefficient \( \gamma \) as a result of the fluctuation-dissipation theorem. This phenomenon has been also studied by Weidenmüller and Zhang [8], and they found such dependence of \( \tau_0 \) on \( \gamma \) also in the overdamped situation, but could not decide clearly the dependence of \( \tau_0 \) on \( U_B \) and \( T \). Our result shows that \( \tau_0 \) is the same for any combination of \( U_B \) and \( T \).

We finally turn to the calculation of neutron multiplicity prior to fission. The decay rates will change as neutrons are emitted due to the cooling of the system, reflected in the temperature dependence of the statistical neutron decay rate and of the fission decay rate \( \lambda = \Lambda / D_B \), where \( D_B \) is proportional to \( T^3 \) [6]. We perform this part of the calculation with a numerical cascade. Let \( Y_s(t) \) be the occupation probability of the \( s \)th nucleus in the neutron decay chain which terminates at the \( s \)th step either by fission or by neutron emission. The lack of available excitation energy \( E^*_s = E^*_s - 2T_s - B_s \) has been excluded due to the neutron emission made impossible due to the lack of available excitation energy \( E^*_s = E^*_s - 2T_s - B_s \). Here \( T_s \) and \( B_s \) are the nuclear temperature and the neutron separation energy of the \( s \)th nucleus, respectively. Then \( Y_s(t) \) satisfies a set of coupled equations

\[
\frac{d}{dt} Y_s(t) = \lambda_n,s - 1 Y_{s-1}(t) - \left[ \lambda_{n,s} + \lambda_f,s(t) \right] Y_s(t) ,
\]

where \( \lambda_{n,s} \) and \( \lambda_f,s \) are the neutron emission rate and the fission decay rate at the \( s \)th step, respectively, and \( \lambda_{n,0} = \lambda_{n,t_0} = 0 \) at the beginning and end of the neutron decay chain. The neutron emission rate is calculated by the Weisskopf formula [16]

\[
\hbar \lambda_n = 2mR^2 \left[ \frac{E^* - B_n}{\alpha} \right] \exp\left[ 2\sqrt{\alpha(E^* - B_n) - 2\sqrt{\alpha E^*}} \right],
\]

where \( m \) is the mass of the emitted neutron and \( R \) is the radius of the nucleus. In order to calibrate this formula, \( \alpha \) is adjusted to give the neutron emission rate of 50 keV/\( \Lambda \) which is calculated in a more elaborate statistical model for \( ^{160}\text{O} + ^{142}\text{Nd} \rightarrow ^{158}\text{Er} \) at 207 MeV and \( J = 65\hbar \) [17]. Also, let \( Y_{s,f}(t) \) be the probability of ending the process with fission at time \( t \) at the \( s \)th step. It then satisfies

\[
\frac{dY_{s,f}}{dt} = \lambda_{f,s}(t)Y_s(t)
\]

and hence when \( t = + \infty \), it becomes

\[
Y_{s,f}(\infty) = \int_0^\infty \lambda_{f,s}(t)Y_s(t)dt .
\]

The neutron multiplicity prior to fission is defined by adding all the neutrons released from the entire decay chain,

\[
\nu(J) = \sum_{s=1}^{s_0} (s - 1) Y_{s,f}(\infty) \bigg/ \sum_{s=1}^{s_0} Y_{s,f}(\infty) ,
\]

where \( J \) is the angular momentum for which the calculation is originally performed and the observed neutron multiplicity \( \nu \) is obtained by taking the average among the participating partial waves.

In Fig. 4, we present our results on the neutron multi-
plicity $\nu$ prior to fission. First, we have solved Eq. (5) numerically assuming $D_B$ does not depend on $T$ along the decay chain. The thin dashed line is obtained by taking $\lambda_f(t) = \Lambda(t)D_{B}$ while the thin solid line is the result of neglecting the transient behavior of the fission decay rate and taking $\lambda_f(t) = \Lambda^0_{\text{num}}D_{B}$, where $\Lambda^0_{\text{num}}$ is the constant stationary value of $\Lambda(t)$ (see the last column of Table 1). These two thin lines clearly demonstrate that the transient behavior in the fission decay rate does not affect the precission neutron number very much. Bhatt et al. have also reached the same conclusion [18]. The reason is as follows. For small values of $D_B$, the neutron decay rate $\lambda_n$ is much larger than the fission decay rate initially (because of the diffusion hindrance). As neutrons are emitted, the system cools, eventually favoring fission because of its lower barrier. On average, the fission occurs when the two decay rates are comparable. Thus, in this limit the initial transit time $t_0$ plays no role. In the unphysical opposite limit of large values of $D_B$, $t_0$ becomes very short compared to the neutron decay lifetime and does not affect $\nu$ either. Therefore, we conclude that most of the enhancement in $\nu$ comes from the reduction of the fission decay rate in the overdamped process [19]. In view of this, we have calculated $\nu$ neglecting the effect of the transient time completely. The thick solid line of Fig. 4 is the calculated result taking the temperature dependence of $D_B$ into account. The fission decay rate of the $\nu$th nucleus is then given by $\lambda_{f\nu} = \Lambda^0_{\text{num}}D_B(T_\nu/T_1)^3$, where $D_B$ is the diffusion coefficient in the parent nucleus $^{158}$Er. This temperature dependence causes emission of up to almost one more neutron than in the case of the temperature independent $D_B$.

Gavron et al. measured the precission neutron multiplicity for the reaction $^{160}\text{O} + ^{142}\text{Nd} \rightarrow ^{158}\text{Er}$ at 207 MeV and reported the value $\nu = 2.7 \pm 0.4$ [2]. However, there has been a conflicting report on the neutron multiplicity by Hinde et al. in their more recent measurement for the same reaction at the slightly lower energy of 178 MeV [3]. They found that $\nu = 4.2 \pm 0.3$. Since $\nu$ is expected to increase with increasing excitation energy [15], the conflict between the two measurements is quite severe. Assuming $\nu$ increases by 0.4 for each 10 MeV of excitation energy [15], the expected $\nu$ at 207 MeV would be 5.4. One might hope that a microscopic calculation of $\nu$ would shed some light on this problem. We examined the recent theoretical predictions for $D_B$ by Bush, Bertsch, and Brown [6]. They obtained $D_B = 3.8 \pm 1.6$ keV/$\hbar$ for $^{158}$Er at $T = 2.5$ MeV which is shown by a shaded area in Fig. 4. The uncertainties in the theoretical $D_B$ are due to the Monte Carlo averages and sums. In

Fig. 4, the data by Gavron et al. (lower rectangle) and by Hinde et al. (upper rectangle) are also shown. From the thick solid line, we can extract the range of $D_B$ corresponding to the two measured $\nu$'s; $D_B$ (Gavron) $= 42.0 \pm 9.0$ keV/$\hbar$ and $D_B$ (Hinde) $= 17.7 \pm 3.0$ keV/$\hbar$. They are larger than the theoretical value of Bush, Bertsch, and Brown by a factor of 11.1 and 4.7, respectively. Clearly, the theory of Bush, Bertsch, and Brown is incompatible with either measurement. Further progress might result from examining other effects of the fission hindrance, for example, the giant-dipole photon spectrum [4]. It would be interesting to see what values of $D_B$ are favored by this data.

In summary, we have solved the Smoluchowski equation for quadrupolar deformations. The solutions exhibit two nice properties which help us to analyze the fission process systematically. One is the scaling relation and the other is an analytical expression for the stationary value of the decay rate. The latter is just the overdamped limit of the well-known Kramers' stationary decay rate. We find that the equilibration time is pretty much the same for any combination of the height of the fission barrier and the nuclear temperature. One of the important results in our calculations is that the transient behavior in the fission decay rate plays a very small role in determining the precission neutron multiplicity, quite contrary to the underdamped process. It is due to the fact that the Smoluchowski equation scales the equilibration time and the fission decay rate in an opposite way. The diffusion coefficient extracted by our calculation from the existing two data is larger by a factor of 5–11 than the theoretical estimation of Bush, Bertsch, and Brown based on their recent derivation of the diffusion coefficient from mixing of Hartree-Fock configurations [6]. On the other hand, we predict that the neutron multiplicity of $^{160}\text{O} + ^{142}\text{Nd} \rightarrow ^{158}\text{Er}$ at 207 MeV which corresponds to the theoretical $D_B$ would be $\nu^{\text{th}} = 6.6 \pm 0.5$, which can be compared to $\nu = 5.4$ extrapolated from the Hinde’s result according to a recent calculation on the neutron multiplicity in terms of the excitation energy [15].

We thank D. Brink for informing us about Ref. [10]. This work was supported in part by the National Science Foundation under Grant No. 90-17077. One of the authors (D.C.) acknowledges support from the Ministry of Education, Korea. He is also grateful to Professor G. F. Bertsch for the warm hospitality extended to him during his visit to Michigan State University.

[19] This result is quite contrary to the underdamped case in the Kramers model where $t_0$ increases as $D_\beta$ becomes larger [13].
